KENTI Nozawa (1995) provided the first detailed description of scientific understanding of the system of relationships between soil pollution and the environment. Her work focused on the interaction between soil pollution and the Earth's atmosphere. In so doing, she established important testable theories and prompted several advances in chemistry. Earth Model can be seen as an overview of the world's knowledge of such relationships between chemistry and the environment.

The basic idea is that the soils that provide food, fodder and shelter for animals have different compounds in them and, consequently, the emissions from animals likewise vary. As these indicators are available for extensive field sampling, we can test the relationships they infer between those indicators and their environment. The other hypothesis is that as these plants grow, their sensitivity to carbon and nitrogen varies. Similar variations in soils and the environment are derived from their reactivity. And for that, the necessary catalyst is natural gas and, most importantly, atmospheric carbon dioxide.

The basis of the general idea on which the above methods are built is the development of principles under which the relationship between the soil and the environment can be probed. These principles range from considerations concerning pH and aqueous content to the unifying concepts of biogeochemical formation, the systematic regulation of different scales of mechanical properties, the domain of earth systems, mineralogy, lipid formation, biochemical propagation, and so on. Gaining accurate information from these theories requires laying the groundwork in the laboratory and generalistic studies of the local case. The testability of the tests relates to the significance of the results obtained by them. Therefore, the robustness of the process of testability of the methods was verified by observing their success in the presence of complete biological systems and in the presence of precise empirical experiments.
